The optimal mineral N fertilizer use (timing and rate) for corn (Zea mais L.) yield has been known to vary regarding different environmental conditions. Previous research has shown that a primary N requirement should be met before the V8 stage, while the first two N applications should occur around seedling and stem elongation. Nonetheless, due to the high spatial variability of irrigated maize crop growth, it becomes rather difficult to assess optimal N application, which simultaneously consider variability of soil N supply (storage and mineralization) and N uptake efficiency. As such, the present study tries to integrate and model all of these factors to evaluate maize yield response to a multitude of possible mineral N treatment combinations (timing and amount). For this purpose, STICS, a stateof-the-art process-based crop model, was used to reproduce temporal changes in the soilcrop mineral N pool at three different sites in Ribatejo, Portugal, over the period of 1986-2005. The first two applications were fixed at the Julian Day (JL) 120 (seedling stage) and at JL 140 (stem elongation), with a typical value of 40 kg/ha. The impact of last N application on yield, ranging from 0-120 kg/ha (10 kg/ha step) and from JL 140-180 (10day interval), was assessed under the historical pedoclimatic conditions. Soil mineralization and N uptake efficiency were also simulated. Our results indicate that JL 150 was the best timing for the third application in all sites. Ribatejo soils presented 200-300 kg/ha of mineralized N and a mean crop uptake efficiency of 65% was found for all possible combinations. Meanwhile, we found that the best amount was of 80-100 kg/ha, depending on the region. In Portugal, the prevailing Mediterranean-like climatic conditions favour the mineralization process, by which a large proportion of crop N demand could be satisfied. Nevertheless, further local field experiments are required to validate and complement our study outcomes.
