

Investigations about the genetic resources of grapes with regard to resistance characteristics to powdery mildew (*Oidium tuckeri*)

by

R. EIBACH

S u m m a r y : During 1991 through 1993 a total of 475 cvs were rated for oidium infection of leaves and berries. It was established that there was no infection of the berries of 41 cvs and on the leaves of one cultivar. A comparison with the *V. vinifera* cvs Müller-Thurgau and Silvaner clearly shows that an impressive number of genotypes have a substantially lower degree of infection. The wide genetic variation offers a good basis upon which new cvs with improved oidium resistance can be bred. Despite the significant correlation between oidium infection on leaves and berries, there was, in many cases, considerable variation in leaf infection within one level of berry infection, or in berry infection within one level of leaf infection. Therefore, a precise conclusion as to the resistance of berries can not be made on the basis of screening procedures in the greenhouse or *in vitro* to determine the degree of resistance on leaves.

K e y w o r d s : gene resources, powdery mildew, resistance, variety of vine.

Introduction

One of the most important fungus diseases world-wide is *Oidium tuckeri*, the pathogen of powdery mildew. In a number of countries around the world there are breeding programmes which seek to develop new mildew-resistant cvs, which are also resistant to powdery mildew. In this type of breeding programme it is vital to determine suitable resistance sources. For this purpose the genetic resources of grapes must be evaluated with regard to suitable carrier of resistance genes. Many authors have dealt with the oidium resistance of different cvs (for literature see ROY and RAMMING 1990). However, it is often difficult to compare the results because they have been attained under different conditions or with different methods. In addition to field observations (BOUBALS 1961; DOSTER and SCHNATHORST 1985; PATIL *et al.* 1990), *in vitro* procedures have also been described as means of evaluating resistance genes (KLEMPKA *et al.* 1984; HEINTZ *et al.* 1985; DIEHL and HEINTZ 1987). Moreover, the results are often limited to only a few genotypes. Therefore, it was the goal of the investigations presented here to evaluate a wide spectrum

of genotypes for their degree of resistance to oidium under the same conditions.

Materials and methods

Over a period of 3 years from 1991 to 1993 the degree of oidium infection on the leaves and berries of plants in the field was determined. Each year the infection observations took place during the period from the end of July to mid-August. Set on of berry ripening occurred within this period for most of the cvs. After the beginning of ripening the berries are rarely infected (DELP 1954; SEEM *et al.* 1990), meaning that the data gathered reflects maximum infection in the course of the vegetation period. This is not true of the leaves. Here the degree of infection may increase in August/September depending on the genotype and the weather conditions. The ratings were done in accordance with the scheme of the OIV (ANONYMOUS 1983). However, the degree of infection was noted instead of the degree of resistance (Tab. 1). This takes into account that infection is subject to fluctuations depending on varying environ-

T a b l e 1
Rating levels for oidium infection of leaves and berries

Level	leaves	berries
1	no infection	no infection
3	small punctuated necrosis; attacked patches clearly limited	small punctuated necrosis; only a few berries on individual clusters attacked
5	spread necrosis with 2 - 5 cm diameter; attacked patches mostly limited	up to about 30% of the berries attacked; no or only very few cracked berries
7	large, extensive attacked patches; some of them still limited	about 50% of the berries attacked; few cracked berries
9	not limited and very extensive attacked patches; most of the entire leaf attacked	more than 70% of the berries attacked; repeated cracked berries

Table 2

The maximum degree of oidium infection of leaves and berries of interspecific crossings; field observations 1991-1993; B/L = berry/leaf. *V. vinifera* cvs for comparison: Müller-Thurgau B/L = 9/7, Silvaner B/L = 9/9

Figure: Climatic data 1991-1993 - deviations from long-term values (1951-80)

mental factors. Thus it may not correspond to the genetic degree of resistance of a genotype. Therefore, the results make it feasible to compare the degree of infection or resistance of the different cvs rather than simply determining the resistance characteristics of one cultivar.

The genotypes have been planted in a testing field at the Institute for Grapevine Breeding Geilweilerhof. This field has been stocked with so-called interspecific crossings exclusively. The field has never been treated with fungicides. The cv. names used here correspond to those by ALLEWEILDT and DETTWEILER-MÜNCH (1992), who also provide further details on each cultivar. For comparison purposes the *V. vinifera* cvs Silvaner and Müller-Thurgau were also cultivated on a neighbouring field without any plant protection treatment and their degrees of infection were ascertained.

In comparison to the long-term mean, temperatures were higher, the amount of sunshine was up, and rainfall was down from May to August during the 3 years of study (Figure). The result was an above-average degree of oidium infection, providing a good situation for collecting data on resistance characteristics under natural infection conditions.

Results and discussion

Tab. 2 shows the mean values of degree of infection on leaves and berries for the 3-year period. The cvs are listed in sequence according to the degree of berry infection, the first showing the least amount of infection (listing of the cvs in alphabetical order: see Appendix). Within each level of berry infection the cvs are listed in order of leaf infection, again the first being the lowest. 41 (= 9 %) out of the 475 cvs tested showed no infection on the berries (Tab. 3) but cv. Dattier precoce de Seibel alone was free of oidium infection on the leaves. No cultivar did show any oidium infection on leaves and on berries during the whole period.

333 cvs (70 %) had a maximum rating of 3 on berry infection. Only 29 cvs showed a rating of ≥ 7 as a maximum for the 3 years, making them comparable to the *V. vinifera* cvs Silvaner and Müller-Thurgau. It was determined that the mean leaf infection was higher. For 256 cvs the maximum infection level was ≤ 3 , whereas 58 cvs had a maximum infection rating of ≥ 7 , which corresponds to the infection ratings of Silvaner and Müller-Thurgau. Similar research

Table 3

Total survey of grouping into oidium infection levels ($n = 475$ varieties) based on the maximum infection ratings during the years 1991 to 1993

Total	41	109	183	48	50	15	19	5	5	475	

done in the field by BOUBALS (1961) includes 76 of the genotypes observed here. Although the ratings can not be compared directly due to different grouping methods, the relation between the genotypes is identical to a great degree. The degree of infection ascertained in this study is generally higher, which may be due to high oidium infection pressure.

The results for the cultivar spectrum tested show a large deviation for oidium infection reflecting the very wide genetic variation of the genotypes tested. Only a very small minority showed a degree of susceptibility similar to the *V. vinifera* cvs. The great majority was considerably less infected by oidium not only on the leaves but also on the berries.

For wine-grape cvs an infection level of 2 for berries or 3 for leaves ought to be tolerable. A total of 114 (24 %) of the genotypes tested show these or lower infection ratings. For breeding purposes there is thus a remarkably wide genetic basis for developing new cvs with sufficient oidium resistance. However no genotypes were found being completely free of infection. This should make it quite difficult to breed new cvs with absolute oidium resistance on the basis of this cultivar group.

A significant correlation ($r=0.54$ (1992) and $r=0.59$ (1993)) can be documented between infection of the leaves

and berries (Tab. 4). However, the coefficients of determination indicate that only between 29 % (1992) and 35 % (1993) of the variation in the berry infection can be explained by the variation in the leaf infection and vice versa. Even if only the maximum ratings are considered, the coefficient of determination is only slightly higher (0.37). The total summary (Tab. 3) points out that the variation in the leaf infection within one level of berry infection is, in some cases, considerable and may deviate as much as 8 rating levels. The situation is similar with regard to the variation in berry infection within one leaf infection level. BLAICH (1987) describes various resistance mechanisms against oidium. The fact that infection of berries and leaves may vary considerably for many genotypes might be due to the differing importance of certain defense mechanisms in the two organs. In view of early diagnosis procedures it is important from a breeding point of view that the degree of infection of the berries can't be inferred from the degree of infection of the leaves with a sufficient degree of certainty. *In vitro* resistance tests of leaf disks (DIEHL 1987) or intact plants can be a valuable screening method for determining the degree of leaf resistance. However, additional tests are required to determine berry resistance exactly.

Table 4

Correlation coefficients and coefficients of determination
for oidium infection on leaves and berries

Year	Correlation coefficient r	Coefficient of determination r^2
1991	0,57	0,32
1992	0,54	0,29
1993	0,59	0,35
Maximum from 1991 - 1993	0,61	0,37
